Abstract:

Seventy five genotypes of safflower representing the broad spectrum of variation were assessed for genetic divergence for eight characters using Mahalanobis D^2 statistic and principal component analysis. The seed yield contributed maximum towards the total genetic divergence followed by test weight and number of seeds per capitulum. On the basis of clustering method, twelve clusters were obtained for D^2 statistic. The best clusters with regard to seed yield and oil content were cluster XII and cluster II, respectively. Principal component analysis identified three principal components which explained 83.02% variability. Genotypes GMU 3470, GMU 3484, GMU 3499, A-1, JSF-1 and GMU 3475 (based on PCI axis) were divergent.

Key words: safflower, D^2 analysis, Principal Component Analysis

Safflower (*Carthamus tinctorius* L.) is an important oil seed crop and its oil constitutes an important source of PUFA in the oil based diets of many people in India. For improvement programme of existing safflower varieties, the selection of suitable diverse parents for hybridization is an important step for getting desired recombinations in the segregating generations. The D^2 classifies the genotypes into homogenous groups / clusters with little diversity within cluster while diversity between two clusters is usually high. Thus representative genotypes from diverse clusters can be earmarked for utilization in hybridization programme depending upon breeding objective. Since, the literature in respect of genetic divergence studies in safflower is meager, present investigation was undertaken to assess the presence of genetic diversity among safflower germplasm lines. Traditionally Mahalanobis D^2 statistic to measure genetic divergence as suggested by Rao (1952) has been used by different workers. The PCA technique has been applied in this study to identify divergent genotypes.

Seventy five safflower GMU lines obtained from Directorate of Oilseeds Research, Hyderabad were sown in Augmented Block Design at Agricultural Research Station, Tandur during rabi 2010-11. The entries were grown in 5 m long single row plots with a spacing of 20 cm between the plants and 45 cm between the rows. Recommended cultural practices were followed to raise a good crop. Five competitive plants from each line were randomly selected for recording observations for seven metric characters viz., days to 50% flowering, days to maturity, number

of capitula per plant, number of seeds per capitulum, test weight (g), seed yield (kg/ha) and oil content(%). Genetic divergence among 75 genotypes was analyzed by using Mahalanobis's D^2 statistic (Rao, 1952) and Principal Component Analysis (PCA) as described by Jackson (1991).

On the basis of D^2 values, the seventy five GMU lines (Table 1) were grouped into twelve clusters with cluster I possessing 26 genotypes followed by cluster III with 14 genotypes, cluster II with 11 genotypes, cluster VI with 9 genotypes, cluster V with 8 genotypes while the remaining clusters i.e., cluster IV, VII, VIII, IX, X, XI and XII consisted of single genotypes as shown in Table 2.

Based upon agglomerative cluster analysis, intra cluster D^2 values ranged from 0.00 (cluster IV, VII, VIII, IX, X, XI and XII) to 10.36 (cluster VI) whereas, maximum inter cluster distance was observed between cluster VI and XII (33.82) followed by cluster VII and XII (33.77) and cluster VI and XI (33.72) while the least D^2 values were recorded between cluster II and cluster IV (8.30) followed by cluster I and VI (9.46) and cluster I and VII (9.89). D^2 statistic revealed (Table 4) that cluster XII recorded highest mean values for number of capitula per plant (23.00), number of seeds per capitulum (30.00) and seed yield (2009.50kg/ha) while cluster II recorded the highest mean values for test weight (5.05 g) and oil content (28.21%). The genotypes falling under these clusters may be tried for direct adoption and hybridization for improvement of yield. These results are in agreement

with earlier findings of Diwakar *et al.*, (2006). Cluster VII recorded the highest mean value for days to 50% flowering (88.50) and days to maturity (118.50), while cluster XI recorded for highest mean values for plant height (89.00). D2 statistic showed that the (Table 5) characters contributing towards divergence revealed that the maximum contribution towards divergence is by seed yield (42.52%) followed by test weight (27.89%), number of seeds per capitulum (12.61%) and number of capitula per plant (8.25%). These four characters altogether accounted for more than 80% of the total divergence in 75 GMU lines studied. Patil *et al.* (1991) and Patel (1990) reported similar findings in safflower.

The distribution of genotypes based on PCA values are shown in 3D plot where the genotypes (37 and 73) and (66 and 22) were away from other genotypes on the basis of PCA I and PCA II scores (Table 6). The first three principal components showed eigene values more than one and they altogether explained 83.78% of the variability. The first PC explained 55.28% of the total variability in the set of all variables and remaining ones accounted for progressively lesser amount of variation.

The above methods of grouping revealed a single concept of non-correspondence of genetic divergence and geographical diversity. The genotypes GMU 3470, GMU 3484, GMU 3499, A1, JSF 1 and GMU 3475 were found divergent. Arunachalam and Bandopadhyay (1984) have proved experimentally more number of heterotic combinations with higher level of heterosis from the parents grouped into moderate divergent groups. Hence, selection of varieties should be more dependent on genetic diversity than the geographical diversity. Similar findings were also reported by Pawar *et al.* (2006).
